OneTogether is a partnership between leading professional organisations with an interest in the prevention of surgical site infection (SSI). The founding partners are:

- The Association for Perioperative Practice (AfPP)
- Infection Prevention Society (IPS)
- College of Operating Department Practitioners (CODP)
- Royal College of Nursing (RCN)
- 3M Company

The partnership is a quality improvement collaborative which aims to promote and support the adoption of best practice to prevent SSI throughout the patient’s surgical journey. We seek to provide resources that make the evidence for practice to prevent SSI accessible to those involved in caring for surgical patients.

Resources created by the OneTogether partnership can be freely downloaded from our website: www.onetogether.org.uk

The OneTogether Quality Improvement Resources are intended to provide practical information for implementing best practice for each of the elements of care across the surgical pathway. These resources can be used as stand alone documents, but we recommend they are used in conjunction with the OneTogether Assessment Toolkit.

The OneTogether Assessment Toolkit is designed to measure adherence to best practice to prevent surgical site infection (SSI). Following completion of the OneTogether Assessment, healthcare professionals will be able to identify areas of low compliance and develop a prioritised action plan for improvement.

Quality Improvement Resources summarise the evidence underpinning recommended practice and provide a competency assessment checklist. The information they contain is drawn from evidence-based guidelines or expert recommendations from professional bodies.

3 Preventing Surgical Site Infection

Surgical site infection (SSI) accounts for more than 15% of all healthcare associated infections and affects at least 5% of patients who have surgery.1 2

Impact of SSIs

Surgical Site Infections are associated with an increase in:3 4

- Patient morbidity and mortality
- Length of stay
- Cost of care
- Readmissions
- Antimicrobial use
- Litigation

How does SSI occur?

SSI occurs when microorganisms introduced into the incision site during the surgical procedure multiply in the wound and cause signs and symptoms such as inflammation or pus, wound breakdown or fever. Symptoms of SSI may take several days to develop and may not become apparent until after the patient has been discharged from hospital. Most SSIs affect only the superficial tissues, but some affect the deeper tissues or other parts of the body handled during the procedure.1 (Figure 2)
There are several factors which increase the risk that an SSI develops (see Figure 3). The most important is the presence of microorganisms at the site involved in the surgery. Procedures that involve parts of the body with a high concentration of normal flora, such as the bowel, are therefore associated with a higher risk of SSI than those involving sterile tissues, such as joint replacements. Rates of SSI vary with different categories of surgery (Table 1).

**Factors that affect the risk of SSI**

Pathogens that cause SSI may originate from:

- the patient’s own microbial flora present on skin and in the body
- the skin or mucous membranes of operating personnel
- the operating room environment
- instruments and equipment used during the procedure
3 Preventing Surgical Site Infection

Rates of SSI vary with different categories of surgery

Microorganisms can be introduced into the incision site during the procedure. They may be directly introduced from the personnel involved in the operation but also indirectly on airborne particles that settle into the open tissues or on to instruments used in the procedure. The longer the procedure the greater the length of time that tissues are exposed to contamination.

The efficacy of the patients’ immune response is also an important factor in determining whether microorganisms in the incision site are able to multiply to cause infection.

The risk of SSI increases with:

- The age of the patient.
- A diminished immune response due to an underlying illness (e.g. diabetes) or immunosuppressive therapy.
- Where local conditions impair healing e.g. obesity.

A surgical technique that minimises damage to tissues and prevents haematoma formation reduces the risk that microorganisms left in the incision site are able to multiply and subsequently cause SSI.

*Based on SSI detected in inpatients and readmissions after surgery

Source: Surveillance of Surgical site infection in NHS hospitals in England, 2015/16
Practices designed to prevent SSI are an essential part of perioperative care and must be applied consistently to ensure the risk of SSI is minimised.

Procedures to prevent SSI are aimed at:

- Minimising the number of microorganisms introduced into the incision site, for example removing microorganisms that normally colonise the skin of patient, maintaining asepsis and managing air quality.
- Preventing the multiplication of microorganisms at the incision site, for example using prophylactic antibiotics.
- Enhancing the patients’ defences against infection, for example by minimising tissue damage and maintaining normal body temperature during the procedure.
- Preventing access of microorganisms into the incision site, for example postoperatively by use of a wound dressing.

Source of guidance on preventing SSI

The most authoritative guidance on the prevention of SSI can be obtained from high quality systematic reviews of research on the efficacy of interventions. In the main these studies are referenced in the following major guidelines:

- National Institute for Health and Clinical Excellence (NICE) guideline (2008)
- Centers for Disease Prevention and Control (CDC) / Healthcare Infection Control Practices Advisory Committee (HICPAC) guidelines (2017)

Advice contained in the OneTogether Improvement Resources has been drawn from these sources and other reviews of similar quality.
Hypothermia, defined as a core body temperature of less than 36.0°C, is a common but preventable complication of surgery. It is associated with a number of adverse outcomes including:

- Increased perioperative blood loss
- Longer post-anaesthetic recovery
- Increased length of hospital stay
- Unanticipated readmission to high dependency units
- Cardiac events including arrhythmia, myocardial ischaemia
- Changes in the metabolism of drugs
- Increased risk of surgical site infection
- Postoperative shivering and thermal discomfort (patient satisfaction)
- Pressure ulcers

Although hypothermia may need to be deliberately induced during some cardiac surgical procedures, inadvertent perioperative hypothermia (IPH) will affect as many as 70% of patients undergoing routine surgery unless active steps to keep them warm are taken.

NICE has also estimated costs associated with IPH, which contribute to an overall increase in the cost of care (see Table 2).

How does the body control temperature?

The core body temperature of blood and internal organs is maintained at a normothermic level (between 36.5°C and 37.5°C) by the thermoregulatory system.

The thermoregulatory system is controlled by the hypothalamus in the brain, which receives information about the body’s temperature from thermoreceptors located across the body. The hypothalamus responds to this information and induces a biological response to maintain temperature within the normothermic range.

Physiological responses to cold temperature include, vasoconstriction (narrowing of blood vessels), non-shivering thermogenesis (an increase in basal metabolic rate) and shivering itself. If the body becomes too warm, physiological responses to reduce temperature include vasodilation (widening of blood vessels) and sweating (see Figure 3).

Thermoregulatory mechanisms

- The hypothalamus regulates the body’s core temperature
- Thermoreceptors are used by the hypothalamus to respond to temperature
- Thermoreceptors are located in:
  > Skin
  > Spinal cord
  > Brain
  > Deep central tissues

Core: 37°C
Periphery: 2-4°C cooler

11.
4 Preventing Inadvertent Perioperative Hypothermia

Surgery and the risk of hypothermia

It is not unusual for the patient's core temperature to drop to below 35°C within the first 30 minutes of anaesthesia if steps are not taken to maintain normothermia. General anaesthesia increases the risk of hypothermia because it inhibits the thermoregulatory response. Both general anaesthesia and regional blocks promote vasodilation of peripheral vessels. Heat is therefore redistributed to the peripheral tissues and lost from the body, subsequently reducing the core temperature (see Figure 4).

Figure 4: Redistribution of heat following anaesthesia

In addition, exposure of tissue and internal organs during surgery and the ambient temperature and airflow in the operating theatre can result in the loss of body heat. Cooling may also be increased by the use of intravenous and irrigation fluids.

Hypothermia is more likely to occur if:

- the patient gets cold or is poorly perfused (i.e deprived of fluids) while waiting for surgery
- a significant surface area of their body is uncovered during surgery

Box 1: Summary of NICE Clinical Guideline CG65 (2008; updated 2016)

Preoperative warming

NICE recommends that all patients should be assessed within the hour prior to surgery for their risk of perioperative hypothermia and their temperature measured using a site that produces a direct measure or direct estimate of core temperature.

All patients should be actively warmed on the ward/emergency department at least 30 minutes prior to induction of anaesthesia. If the patient’s temperature is below 36°C or they are at high risk of hypothermia, they should be warmed immediately.

The patient’s core temperature should be 36°C or above before they are transferred to theatre, unless there is a need to expedite surgery.

Intraoperative warming

Induction of anaesthesia should not begin unless the patient’s temperature is 36.0°C or above (unless there is a need to expedite surgery).

Patients having anaesthesia for longer than 30 minutes, or at a higher risk of perioperative hypothermia are warmed from induction of anaesthesia using forced-air warming.

The patient’s temperature should be measured and documented before induction of anaesthesia and then every 30 minutes until the end of surgery, using a site that produces a direct measure or direct estimate of core temperature.

Intravenous fluids (500 ml or more) and blood products should be warmed to 37°C using a fluid warming device and irrigation fluids should be warmed in a thermostatically controlled cabinet to a temperature of 38°C to 40°C.

Postoperative warming

The patient’s temperature should be monitored and documented every 15 minutes in recovery. The patient should not be transferred to the ward, until their temperature is 36°C or above.
4.1 Temperature Monitoring

Why should you measure a surgical patient’s core temperature?

As hypothermia occurs, heat from the core body is redistributed to the periphery, which in turn increases the mean skin temperature. This can result in the patient feeling warm, even though cooling is actually taking place. Obtaining an accurate measurement of core temperature is therefore essential to identify patients affected by IPH before, during and after surgery and to ensure perioperative warming is commenced as soon as possible.

In some instances therapeutic hypothermia can be induced, whereby the patient is cooled under controlled conditions to 32-34°C. This is often used in comatose cardiac arrest survivors, head injury, and neonatal encephalopathy to protect the patient from hypoxic brain injury. Continuous core temperature monitoring is essential in these instances, to ensure that mild hypothermia in maintained, and cerebral damage is minimised.

How should you measure core temperature?

There are a range of devices that are able to measure core temperature, with varying degrees of accuracy. NICE recommends the measurement of temperature at sites which are able to:

- directly measure core temperature or
- directly estimate core temperature to within ±0.5°C.6

Many commonly used devices indirectly estimate core temperature (by measuring the temperature at the periphery) and adding a correction factor. This correction factor can markedly differ between different devices and at different temperatures. Their lack of accuracy could lead to IPH not being recognised and increase the risk of adverse outcomes and resource use associated with hypothermia. As a result of this inaccuracy, indirect estimates of temperature are not recommended by NICE for use in surgical patients.6

NICE identifies that the pulmonary artery catheter; distal oesophageal and urinary bladder are considered the most accurate methods and sites for direct core temperature measurement or direct estimation of core temperature. However, these sites may not always be appropriate for use due to their invasive nature. If an invasive method of core temperature monitoring is not appropriate, other direct methods to estimate core temperature should be used6 (see Table 3).
4.1 Temperature Monitoring

When should a surgical patient's core temperature be measured?

**Preoperatively**
Within 1 hour prior to induction of anaesthesia

**Intraoperatively**
Every 30 minutes

**Postoperatively**
Every 15 minutes in recovery
Every 4 hours on the ward

---

**Box 2: Clinical evidence to support efficacy of differing core temperature monitoring sites and devices**

NICE reviewed 24 studies to identify the best site and method for accurately measuring temperature in the different phases of perioperative care.9

The method and sites of measuring “true” core temperature were identified as pulmonary artery catheter (PAC), oesophagus and bladder. Therefore studies involving comparisons to these three reference methods and sites were included in the review.

The committee highlighted that for most comparisons, only one study contributed towards the evidence base, and this introduces uncertainty into the evidence.

The evidence on indirect estimation of core temperature (temporal artery, infrared forehead, forehead strips, tympanic infrared) indicates that there is a lack of accuracy compared to direct methods.

In cases where invasive core temperature monitoring is not appropriate, the committee noted that other direct methods to estimate core temperature measurement, accurate to within 0.5°C of true core temperature, should be used.
4.1 Temperature Monitoring

Table 3 – Sites of core temperature measurement

As well as considering accuracy in measuring core temperature, the ability to continuously monitor temperature and the invasiveness of the device should also be taken into account.9

* Be aware of possible inaccuracies in core temperature estimation when using peripheral sites, such as sublingual or axilla, in patients whose core temperature is outside the normothermic range (36.5°C to 37.5°C).

Note: Nasopharyngeal is regarded as a good direct estimation of core temperature; however, no evidence was identified comparing nasopharyngeal site of measurement to any of the three reference methods and sites (pulmonary artery catheter, oesophageal or urinary bladder) therefore no recommendation was made about this site of temperature measurement.2
Why should patients be warmed preoperatively?

The pre-operative phase is defined as the 1 hour before induction of anaesthesia (when the patient is prepared for surgery on the ward, admission area or in the emergency department).

During the first 30 to 40 minutes of anaesthesia, a patient’s temperature can drop to below 35.0°C due to cold environmental conditions and an impaired thermoregulatory response under general or regional anaesthesia.

It has been reported than an average core temperature drop of 1.6°C can occur in the first hour of general anaesthesia.8

When the patient is awake, there is a natural temperature gradient between the core and the periphery (skin) of about 2-4°C.8 Warming the surface of the body reduces this gradient and increases the overall heat content of the body, so that the initial drop in temperature on induction of anaesthesia is reduced.

Preoperative warming was found to be highly likely to be cost effective because benefits of preventing hypothermia outweigh the additional cost of the consumables required to prewarm.9

What patients are at high risk of inadvertant perioperative hypothermia?

In the hour before anaesthesia assess all patients for risk factors that can contribute towards perioperative hypothermia and take their temperature.

Patients should be managed as high risk if two or more of the following apply6:

• an ASA grade II to V (see table 4)
• is having combined general and regional anaesthesia
• is undergoing major/intermediate surgery
• is at risk of cardiovascular complications
• a preoperative temperature below 36°C
# 4.2 Preoperative Warming

<td>A patient with severe systemic disease that is a constant threat to life</td>
<td>Examples include (but not limited to): recent (greater than 3 months) MI, CVA, TIA, or CAD/stents, ongoing cardiac ischemia or severe valve dysfunction, severe reduction of ejection fraction, sepsis, disseminated intravascular coagulation (DIC), acute respiratory distress (ARD) or ESRD not undergoing regularly scheduled dialysis.</td>
</tr>
<tr>
<td>ASA V</td>
<td>A moribund patient who is not expected to survive without the operation</td>
<td>Examples include (but not limited to): ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the face of significant cardiac pathology or multiple organ/system dysfunction.</td>
</tr>
</tbody>
</table>
4.2 Preoperative Warming

Which patients should be warmed preoperatively?

All patients should be actively warmed on the ward/emergency department at least 30 minutes prior to induction of anaesthesia. If the patient’s temperature is below 36°C or they are at high risk of hypothermia, they should be warmed immediately.

The patient’s core temperature should be 36°C or above before they are transferred to theatre, unless there is a need to expedite surgery.6 (See Appendix B).

Box 3: Summary of clinical evidence to support preoperative warming

- Twelve studies including 1281 participants contributed data to the analysis considered in NICE guidance CG65. The quality of and certainty in the evidence for each outcome ranged from very low to moderate.
- Preoperative active warming was found to be significantly more effective than no preoperative active warming for critical outcomes (core temperature at end of surgery, 30 minutes, 60 minutes, 120 minutes, surgical & wound infections and hypothermia).
- There was no significant difference for the other outcomes reported (shivering, adverse effects, blood transfusion and cardiac complications).
- An economic analysis found that preoperative warming had a 98% probability of being cost effective. Using forced air warming both pre and intraoperatively was cost effective compared with just using forced air warming intraoperatively.6

What devices can be used to actively warm patients?

Active warming is a process that transfers heat to the patient rather than passively keeping them warm. Active warming is essential for patients undergoing surgery in order to prevent them developing IPH. An approach based on convection (forced air warming) or conduction (resistive heated mattress or blanket) is recommended.

Active warming devices

Convective warming
Involves heat transfer due to gentle dispersion of warmed, filtered air across the patient’s skin. Examples include:
- Forced-air warming blankets
- Forced-air warming gowns

Conductive warming
Involves heat transfer due to surface-surface contact between the heating device and the patient. Examples include:
- Electric blankets
- Electric heated pads
- Radiant heating
- Resistive heating mattresses
- Resistive heating blankets
- Warming pads
4.3 Intra and Postoperative Warming

Why should patients be warmed intra and postoperatively?

The intraoperative phase is defined as the total anaesthesia time, whilst the postoperative phase is defined as the 24 hours after admission into the recovery area and includes transfer to and time spent on the ward.

Due to the effects of general anaesthesia and cold environmental conditions (see figure 5), the patient is susceptible to IPH throughout the perioperative phase.

Warming a patient reduces the gradient between the periphery and core, and therefore increases the overall heat content of the body.

The aim of warming throughout the intra and postoperative phases is to maintain a normothermic temperature, and thereby reduce the risk of adverse effects associated with IPH.

Which patients should be warmed intra and postoperatively?

Patients should be actively warmed, using a forced air warming device from the induction of anaesthesia, who meet at least one of the following criteria:

- have been assessed as at high risk of perioperative hypothermia
- have a core temperature below 36°C
- whose anaesthesia is expected to last longer than 30 minutes

Figure 5: Cold environmental conditions

- Theatre temperatures are 18-22°C
- During preparation and surgery, large areas of skin are exposed to the cold operating room
- Surgical incisions expose internal organs
- Length of surgery
- Blood and fluid loss
- Wet skin preps
4.3 Intra and Postoperative Warming

How should patients be warmed intra and postoperatively?

All patients should be kept covered to reduce heat loss and the ambient temperature of the operating theatre should be maintained at least 21°C.

If patients require warming intra or post-operatively (in recovery and on the ward), then active warming using forced-air should be implemented.

Temperature should be monitored every 30 minutes during surgery, every 15 minutes during recovery and every 4 hours on the ward. If the patient’s core temperature drops below 36°C at any time, then forced-air warming should commence.

Facilitating patient movement may be a consideration when selecting a method of active warming preoperatively. The type of preoperative warming device used will therefore depend on the individual patient, the setting, the operation and the hospital.

If forced-air devices are considered unsuitable for a specific patient or procedure then a resistive heating mattress or blanket can be used instead.

Intraoperative forced air warming has been found to be more likely to be cost effective compared with resistive heating mattresses and blankets.6

Box 4: Summary of clinical evidence to demonstrate efficacy of different active warming methods intraoperatively

NICE reviewed 26 studies comparing forced air warming with other active warming methods during the intraoperative phase. A focus on forced air warming and resistive heating was undertaken as both of these methods are used in clinical practice in England and Wales, whereas the other active warming methods are no longer routinely used.

The studies all differed with regards to the devices used, the temperature used, the location of core temperature measurement and the proportion of the body that the warming device covered.

The evidence for the comparisons of interest in the intraoperative period (forced-air warming versus resistive heating) ranged from very low to high quality.

Meta-analysis of 18 studies with 1029 participants found that forced air warming was more effective than resistive heating mattresses.6

Meta-analysis of 6 studies after a sensitivity analysis found that forced-air warming was more effective than resistive heating blanket at end of surgery but there was no difference at the different timepoints during surgery.5

For other outcomes such as cardiac events, blood loss and SSI, differences between methods of active warming were not significant, although many of the studies were small in size and underpowered to detect the relatively rare events.
Why should intravenous and irrigation fluids be warmed?

If a patient is in receipt of a large volume of intravenous fluids (i.e. fluids administered into veins) and/or irrigation fluids (fluids used to wash parts of the body) then their temperature can impact the patient’s core temperature.

If the temperature of these fluids is below core body temperature, they can cause significant heat loss.

Warming intravenous and irrigation fluids to core body temperature or above might prevent some of this heat loss and subsequent hypothermia.13

How should intravenous fluids be warmed?

In a recent review of clinical evidence, it was found that warmed intravenous fluids kept the core temperature of study participants about half a degree warmer than that of participants given room temperature intravenous fluids at 30, 60, 90 and 120 minutes, and at the end of surgery.13

Warmed intravenous fluids also further reduced the risk of shivering compared with room temperature intravenous fluids.13

The degree of warming produced by warming fluids may be related to both the volume infused and the rate at which it is delivered.13

Intravenous fluids (500 ml or more) and blood products should be warmed to 37°C using a fluid warming device.6

How should irrigation fluids should be warmed?

Evidence suggests that the body cavity irrigated, along with temperature, volume and duration of irrigation, is likely to impact core temperature by transferring heat from the body to the solution.13

However, a review of current evidence shows that there is no statistically significant differences in core body temperature or shivering between individuals given warmed and room temperature irrigation fluids. However, this evidence is described as weak.5, 13

Based on all evidence, NICE recommends that all irrigation fluids used intraoperatively should be warmed to a temperature of 38–40°C in a warming cabinet.6

Irrigation warming devices are able to provide a consistent temperature of fluids administered, however current practice relies on warming cabinets, which need to be used with caution (see Box 5).

Appendix A: Standards and Guidance

Reducing the risk of Surgical Site Infection (SSI)

1. Skin Preparation
1.1 Washing
Recommendation
NICE recommends that patients should shower or have a bath (or be assisted to shower) within 24 hours of admission, either the day before, or on the day of surgery.(1)

1.2 Hair Removal
Recommendation
NICE recommends that neck should not be shaved for hair removal because they increase the risk of SSI. If must be removed, then clippers with disposable heads are recommended.(1)

1.3 Skin Disinfection
Recommendation
NICE recommends that the skin should be disinfected immediately prior to the incision with chlorhexidine or povidone-iodine (alcoholic solution).(1)

1.4 Reducing Skin Recolonisation
Recommendation
NICE recommends that an effective antiseptic should be used, this should be effective in reducing bacterial population on skin,(1)

2. Prophylactic Antibiotics
Recommendation
NICE recommends that patients should have an antibiotic administered preoperatively and continued intraoperatively. Surgical patients should have an antibiotic administered preoperatively and continued intraoperatively. Surgical prophylaxis should be given intravenously within 30-60 minutes after the incision is made.(2)

3. Perioperative Warming
Recommendation
NICE recommends that all patients should be warmed from induction of anaesthesia using a site that produces a direct measure or direct estimate of core temperature. Active warming should commence on the ward/emergency department at least 30 minutes prior to induction of anaesthesia for all patients (and immediately if their temperature is below 36°C). The patient's core temperature should be 36°C or above before they are transferred to theatre, unless there is a need to expedite surgery. The patient's core temperature should be 36°C or above before they are transferred to theatre, unless there is a need to expedite surgery. The patient's core temperature should be 36°C or above before they are transferred to theatre, unless there is a need to expedite surgery. The patient's core temperature should be 36°C or above before they are transferred to theatre, unless there is a need to expedite surgery.

4. Maintaining Asepsis
Recommendation
All pre sterilised instruments must be checked for evidence that they have been sterilised and that the packs are intact. Instruments should be set up in a clean area, as close to the procedure time as possible. All prepared instruments must be closely observed at all times. The patient's temperature should be measured and documented before induction of anaesthesia and then every 30 minutes until the end of surgery. The patient's temperature should be measured and documented before induction of anaesthesia and then every 30 minutes until the end of surgery.

5. Surgical Environment
Recommendation
An effective air changing ventilation system should be in operation and regularly monitored. The doors to the operating theatres should remain closed and traffic in and out of theatres restricted to a minimum to ensure efficiency of the ventilation. The number of personnel present in theatre should be kept to a minimum.(1)

6. Wound Management
Recommendation
NICE recommends that surgical incisions should be closed with an appropriate interactive dressing at the end of the operation.(1)

7. Surveillance
Recommendation
The risk of SSI should be monitored using a standardised surveillance methodology to provide feedback to surgeons and the surgical team about the quality of infection prevention in the operating theatre. Monitoring of infection rates is essential to provide feedback to surgeons and the surgical team about the quality of infection prevention in the operating theatre.
Appendix B: Perioperative Warming - Decision Guide

The Facts About Perioperative Hypothermia:
Clinical hypothermia - core temperature less than 36°C

Patients can lose up to 1.6°C core temp within the first 1 hour of anaesthesia.
70% of patients experience hypothermia unless steps to keep them warm are undertaken.

Hypothermic patients are associated with:
- Redinision to high dependency units
- Increased surgical site infection rates
- Higher overall costs of treatment
- Cardiac events
- Changes to metabolism of drugs
- Longer post-operative recovery
- Post-operative shivering and thermal discomfort

Who is at risk?
- Any patient undergoing a surgical procedure anticipated to require more than 30 minutes of anaesthesia time
- Any patient undergoing anaesthesia anticipated to last less than 30 minutes who:
  - has an ASA grade greater than 1
  - is having combined GA and regional anaesthesia
  - is undergoing major/intermediate surgery
  - is at risk of cardiovascular complications
  - Has a pre-operative temperature below 36°C

ASA grading:

<table>
<thead>
<tr>
<th>ASA Classification</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASA I</td>
<td>A normal healthy patient</td>
</tr>
<tr>
<td>ASA II</td>
<td>A patient with mild systemic disease</td>
</tr>
<tr>
<td>ASA III</td>
<td>A patient with a moderate systemic disease</td>
</tr>
<tr>
<td>ASA IV</td>
<td>A patient with severe systemic disease</td>
</tr>
<tr>
<td>ASA V</td>
<td>A patient who is at extreme risk and is anticipated to experience life-threatening complications without intervention</td>
</tr>
</tbody>
</table>

ASA Classification:

- ASA I: A normal healthy patient
- ASA II: A patient with mild systemic disease
- ASA III: A patient with moderate systemic disease
- ASA IV: A patient with severe systemic disease
- ASA V: A patient who is at extreme risk and is anticipated to experience life-threatening complications without intervention

The pre-operative phase is defined as 1 hour before induction of anaesthesia.

Start forced-air warming.

The intra-operative phase is defined as the total anaesthesia time (including the time in the anaesthetic room before induction of anaesthesia).

Measure and document the patient's core temperature every 30 minutes.

The post-operative phase is defined as 24 hours after the patient enters the recovery area.

Warm to a temperature of 37°C using a fluid warming device.

Warm irrigation fluids to a temperature between 38-40°C.

Start forced-air warming until the patient's temperature is above 36°C.

Measure and document the patient's core temperature every 4 hours while in recovery.

Measure and document the patient's core temperature every 15 minutes while in recovery.

Patient can be assessed for discharge.

Supported by
The Association for Perioperative Practice is a registered charity working to enhance skills and knowledge within the perioperative arena. For more than 50 years they have promoted best practice and standards of care within this area and currently represent 6,500 theatre practitioners from across the UK and overseas.
www.afpp.org.uk

The Infection Prevention Society is a registered charity whose mission is to inform, promote and sustain expert infection prevention policy and practice in the pursuit of patient or service user and staff safety wherever care is delivered. Its vision is that no person is harmed by a preventable infection.

The College of Operating Department Practitioners is the professional body for operating department practitioners (ODPs). It provides guidance on professional and educational issues to members of the profession, and advises a broad selection of national and local bodies on matters relating to operating department practice. It represents more than 5000 members throughout the UK and overseas, and hosts regular seminars and other public events.

The Royal College of Nursing is the UK’s largest nursing professional body and trade union representing more than 430,000 nursing staff. Founded in 1916, the RCN has worked for more than 100 years to improve nursing education, develop and share good practice and promote nursing as a profession. The RCN Perioperative Forum and the Infection Prevention and Control Network support nursing staff working in settings where surgical care is given.

Health care is evolving rapidly. Changing reimbursements. More stringent patient requirements. New care delivery models. 3M understands your challenges and strives to make your job easier with reliable, quality products and solutions. We help you see more patients at lower costs, while improving overall health. That’s health care progress made possible.
